Text analysis for data science · Research poster

Trump, Iran & the language of conflict

Six rhetorical frames in Truth Social posts before, during, and after selected conflict dates.

Sean Ryan

NC State University

DSA 495 · Fall 2026

Repository snapshot
Feb 28 – Jul 24, 2026

87 unique posts scored · **26** selected conflict start dates · **129** post / event-date pairs · **6** rhetorical frames

Principal finding

Victory scores peak on event days. Threat scores decline across windows.

Across all available date groups, mean Victory scores rise from 0.673 before to 0.761 on the event day, then fall to 0.700 after. These are descriptive model outputs; frame accuracy has not been established.

01 Question & workflow

Do rhetorical frames differ around conflict dates? Political posts can mix threats, success claims, and negotiations. Comparing those frames may help readers examine how public messaging changes around selected events.

Task. Given an Iran-related post, assign six independent frame scores, then compare the day before, day of, and day after an event's recorded start date.

1. **Collect & align**
   Prepared public-post CSV + UCDP-derived event workbook. Match Eastern Time calendar dates to event start dates at −1, 0, +1 days.
2. **Prepare the text**
   Use saved `content_text`; deduplicate by post ID. Preserve case and punctuation. Keep one post / event-date pair.
3. **Represent & classify**
   BART tokenizer → contextual representations → `facebook/bart-large-mnli`. Six natural-language frame descriptions; multi-label NLI, truncation enabled.
4. **Aggregate & compare**
   Average post scores within each event-date/window, then average those date means. Include every available post; a date does not need posts in all three windows.

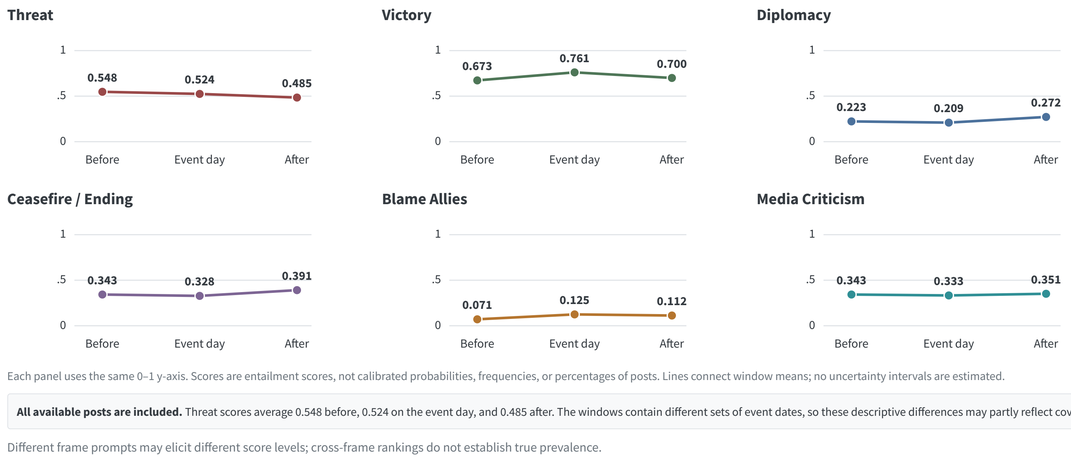

The classifier sees post text only. Event headlines, fatalities, and severity do not enter the model. A post may receive several high scores.

02 Results

Mean frame score by window

Figure 1 · 0–1 scale

All available posts · 20 / 21 / 21 contributing dates · 40 / 40 / 49 post-event pairs (before / event day / after)

Each panel uses the same 0–1 y-axis. Scores are entailment scores, not calibrated probabilities, frequencies, or percentages of posts. Lines connect window means; no uncertainty intervals are estimated.

All available posts are included. Threat scores average 0.548 before, 0.524 on the event day, and 0.485 after. The windows contain different sets of event dates, so these descriptive differences may partly reflect coverage.

Different frame prompts may elicit different score levels; cross-frame rankings do not establish true prevalence.

03 Quality & interpretation

Preliminary · human evaluation pending

What was checked. All 87 score IDs match the post corpus; all six score columns are finite and within 0–1. Post/event pairs are unique and relative days match saved Eastern Time dates.

What remains untested. No human labels, held-out precision/recall/F1, or evaluated baseline are supplied. Data-integrity checks do not measure rhetorical accuracy.

A failure mode to investigate

A post praising the military operation receives a high Ceasefire / Ending score even though the text does not explicitly say the fighting has ended.

Ceasefire / Ending **0.802**

Inspect source post ↗ · Qualitative inspection, not a gold label.

Limits & responsible use

Association only. These selected windows cannot establish causation or predict military action. Same-day dates do not prove that a post preceded an event within that day.

Overlapping windows reuse posts and create dependence. Missing posts are not zero rhetoric. Linked headlines and media-only posts can distort attribution; truncated text can lose context.

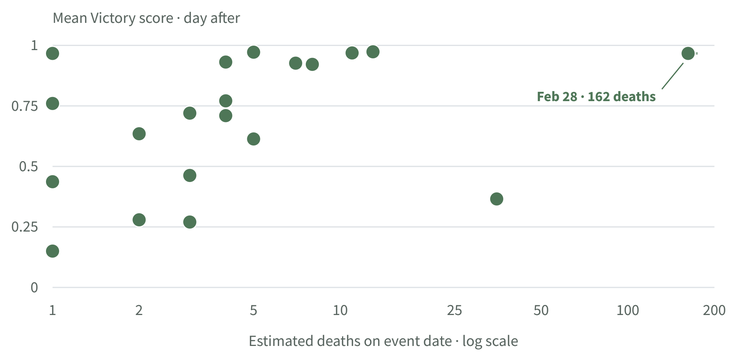

Practical implication. Use the scores to locate language worth inspecting alongside its source. Human validation and a non-event comparison are needed before stronger claims.

Exploratory result · Event severity & rhetoric

Higher Victory scores after deadlier event dates

In this sample, posts the next day tended to receive higher Victory scores after dates with more recorded deaths.

Victory language in next-day posts

One dot = one event date · Next-day post averages · All 20 eligible dates included

Each dot represents one event date with same-day UCDP fatality records and at least one post the following day. The x-axis uses a log scale; horizontal marks show source low–high death estimates, not confidence intervals. Victory is a mean model score (0–1), not a percentage of posts. Multi-day fatality totals and windows without posts are omitted.

+0.50 Spearman ρ · **20** event dates

A moderate positive association

Higher death counts generally align with higher next-day Victory scores. The points still vary widely: this is a tendency, not a rule.

Beyond the largest event date

Without February 28 (162 estimated deaths), the association remains positive: **ρ = +0.43 · 19 dates**.

Worth investigating, not confirmed. This pattern was selected after comparing several frames and windows. Some posts recur across dates, and frame accuracy has not been tested. It does not establish causation or prediction.

Sources & reproducibility. Project repository, prepared CSVs & notebook · UCDP data access · BART-MNLI model · Matching public-post archive. The original post-archive snapshot and model revision remain unpinned; workbook release labels are recorded with the evidence. Counts refer to this repository, not the later portfolio dataset. UCDP requires attribution under CC BY 4.0; underlying post rights remain with their owners.

AI-use statement. The repository's notebook, prepared data, and saved scores preceded this poster task. OpenAI Codex inspected the rubric and code, built this page and reproducible aggregation, and checked joins, dates, counts, and rendered behavior. BART generated the saved analytical scores; it was not rerun for this poster. Sean directed the project. Human review and oral defense remain Sean's responsibility. See the repository for the fuller history.
